Johnson City Parks and Recreation Economic Impact Analysis

****Abstract****

This study aims to perform an Economic Analysis on behalf of the Johnson City Parks and Recreation Department. Our partner, the Parks and Recreation Department of Johnson City, wants to know what the effect on tourism a planned park expansion will have on the region. The park expansion will consist of 4 new baseball/softball fields, and 6 soccer fields. This will bring the parks total amenities to 9 baseball/softball fields and 8 soccer fields. It is also important to note that the expansion will consist of entirely artificial play surfaces. Being that the park expansion will be an additional input for the regions tourism numbers overall, the parks department naturally wants to know what the expected economic impact will be on the region due to this increase in tourism. To perform this analysis we will be relying on information from a variety of sources in order to construct a table of known expenditures. From there, we will make use of the RIMS II multiplier tables which are generated using an I/O model of the region. This will allow us to create region specific impact estimates that we can share with the parks department, and they in turn can use to share with interested parties. This will also allow the park department to have estimates as to how this project will impact their bottom line. First and foremost we will be discussing the data as we received it from the parks and rec department. Second, we will cover the secondary studies used as reference for our own. Third we will cover preliminary calculations made using methods outlined in these secondary studies. Fourth, we will be talking about the Input/Output models and the RIMS II tables which will be utilized later in the study. And lastly, fifth, we will be talking about where the project will be going from here.

Part 1 The Data

Initially for this study we were presented with minimal information from the parks department itself. We received data for the 2022 and 2023 baseball seasons and the maintenance charged for the use of the baseball fields. The data was in the form of a word document and only contained the number of teams, the date of the tournament, and the amount charged to the director of the tournament for use of the fields. This was less than what we had hoped to get our hands on, but the none-the-less it was a start. To begin with, we took the data received and put it into the form of a table so that it was more readable in a raw format as well as making it compatible with software packages like R, Python, or Eviews. Additionally, we referred to some secondary studies in order to pad out the data further with such information as initial party spending estimates or non-local percentage of attendees. We will cover this secondary information in Part 2, but for now, our focus will remain on the initial data.

```
## # A tibble: 6 x 10

## 6	0	0	0	0	0	0	4	0	0	0

A brief breakdown of the data set created so far:

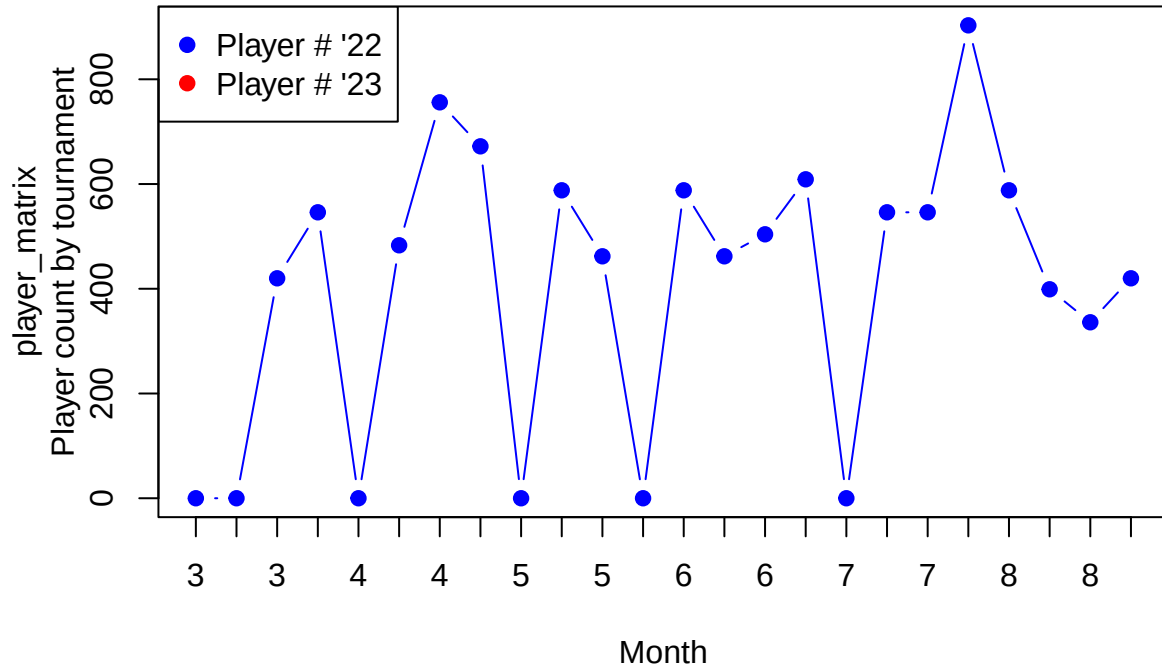

- * days: The duration of the tournament in days
- * teams: The number of teams participating in a tournament
- * fee: The fee charged to the tournament director for use of the park
- * labor: The labor cost associated with running the tournament
- * material: Material cost associated with running the tournament
- * combined: Combined Labor and Material cost
- * month: the month in which the tournament took place
- * players: The number of players participating in the tournament (extrapolated information)
- * spending: Average spending per tournament calculated using information from secondary study
- * nonlocal: The adjusted spending amount assuming 89% nonlocal tournament participation rate (obtained from secondary study)

From a glance at the summary statistics for the information, we can gain some insight into the behaviour at the parks. For instance, we can see that the median number of days for park tournaments is 1 day. We can also see that the mean number of teams is ~19.93 per tournament, and that they were charged on average 643 dollars to participate in the tournament. When looking at player counts we can see that on average each tournament brings around 419 players to the region. Lastly, we can see from data provided, the average initial estimates for expenditures put the average at around \$142,314 per tournament. This table as configured includes data for both 2022 and YTD 2023. When 2021 data is provided from the park the data will be added to the table and used in any additional analysis.

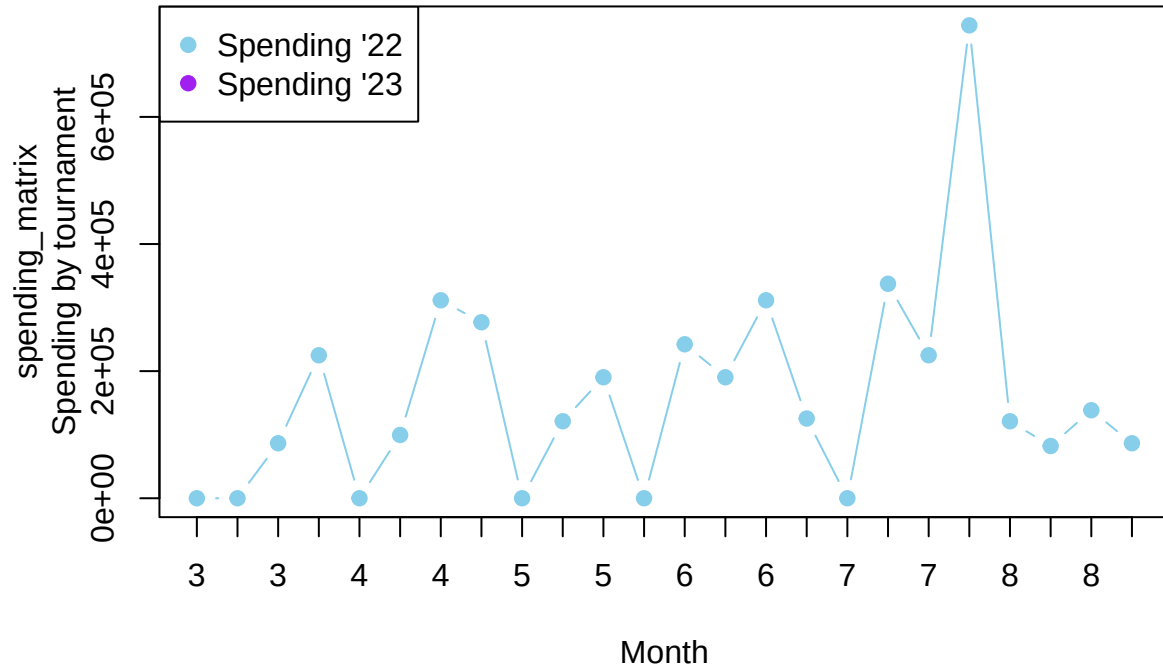

Here we can see a graph that compares the two years of data by month:

Player Comparison 2022vs2023

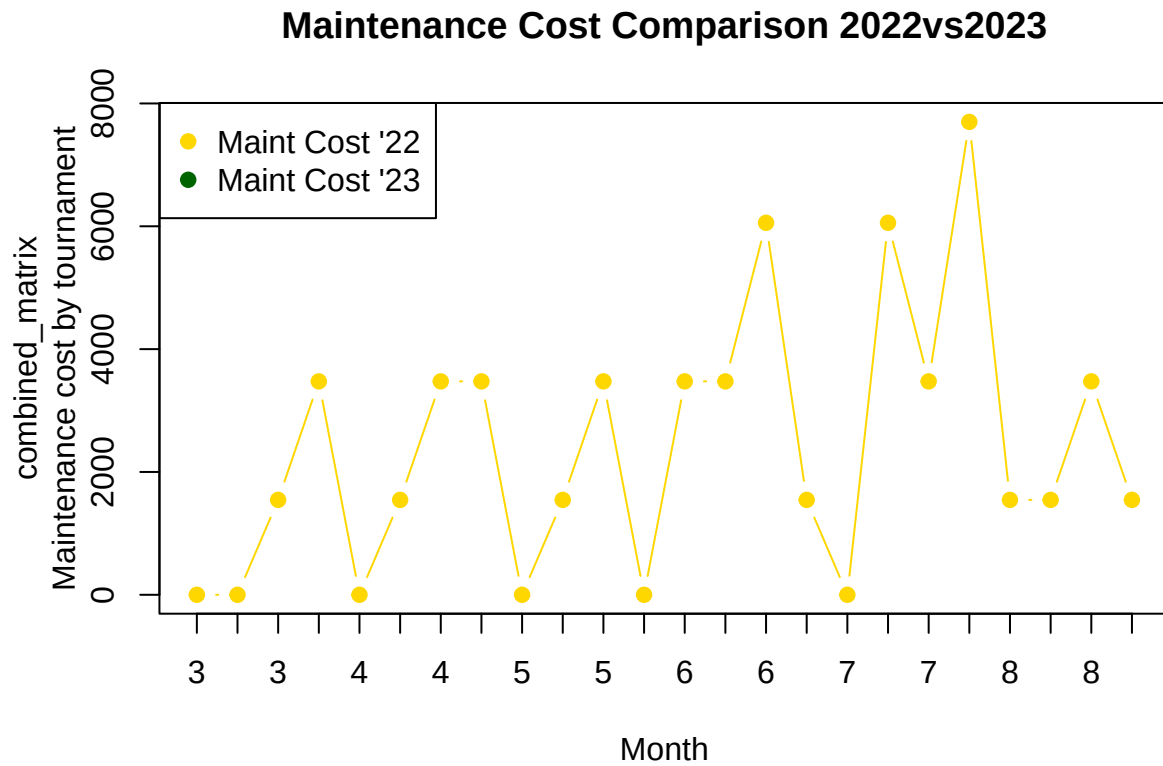

Looking at the graph, we can see that the lines tend to follow similar patterns, remaining fairly constant throughout the season with peaks at the beginning and end. This coincides with the scheduling of baseball/softball, with the start of the season usually being late march and the end of the season being in August/September. Here we can notice that the demand for the fields seems to be fairly constant throughout the baseball/softball season. The zero player counts that are observable are due to rain-outs, in which the tournament was cancelled due to unplayable conditions. The numbers are a little lower for the second half of the season for '23, however any suggestion as to why this has occurred is beyond the scope of this report. Looking at additional visualizations, we can likewise compare spending by year.

Spending Comparison 2022vs2023

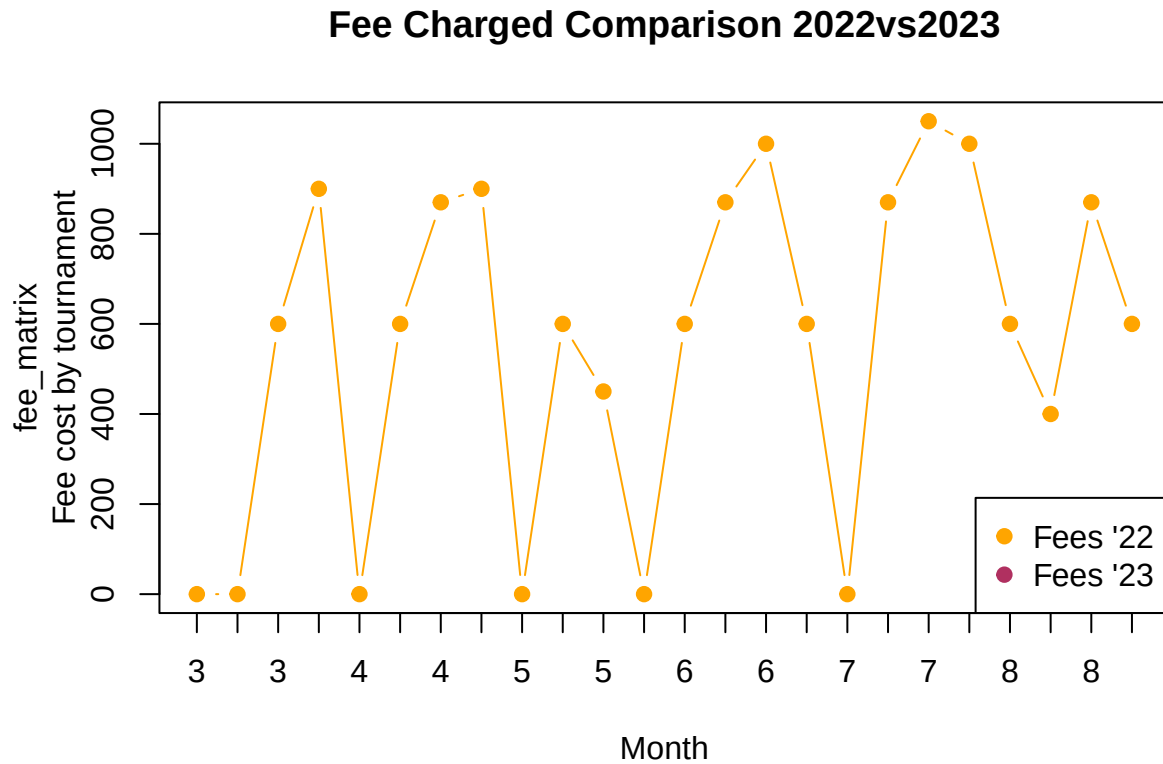

Unsurprisingly we can see that the spending per tournament closely mimics that of the number of player per tournament, intuitively suggesting that the more players there are in a given tournament the more spending occurs in the region. We can also see, again, rather intuitively, that if the tournament does not take place then there is no spending in the region because there are no players in the region. We can also observe that on the average, spending remains fairly constant throughout the season after an initial peak at the beginning of the season (relatively speaking).

We can also look at material cost comparisons between year, though it should be noted that all material cost are essentially constant so this really only shows the difference in tournament type(1,2,3 day) over the two years more than anything else. If more data was available for per tournament cost then a more robust graph could be made with this particular data.

Looking at the maintenance cost comparisons, we see the expected behaviour, where the most we can pull from this is how many of each type of tournament occurred. This is known due to the cost associated with each tournament, where the 1 day tournaments cost ~2000, the 2 day tournaments cost ~3800, the 3 day tournaments cost ~6000, and the 4 day tournament is calculated to have cost ~8000. We can see that 2023 appears to have had a greater number of 2 day tournaments when compared to 2022. There have been no large peaks with a four day tournament so far in 2023.

Lastly, we can look at the fees charged to the tournament directors between the two years.

Looking at the fee comparison between 2022 and 2023, we can see that 2023 actually seems to trend somewhat higher in the average price charged to the tournament directors, relative to the same month. Overall the difference is:

```
## [1] NA
```

```
## [1] NA
```

```
## [1] NA
```

The average for 2022 is 554 dollars and the average for 2023 is 766. This is a 212 dollar increase over the previous year. This is inline with expected cost increases and adjusting pricing to accurately reflect the cost of maintenance.

Part 2 The Secondary Studies

Ok, so now we have some numbers, but now what do we do with them? As we are not well versed in economic impact estimation, we turned to some secondary studies. The most important of these has been “Inexpensively Estimating the Economic Impact of Sports Tourism Programs in Small American Cities” by Brewer and Freeman. This study has been essential to our progress for a multitude of reasons. First and foremost it summarizes the steps required to perform an analysis using its methods, and this summary is clearly laid out. Secondly, it gives us additional information to use in our own study. Third, it has highlighted the need for a certain degree of reliance upon secondary studies to complete the analysis as a full fledged analysis independent of these studies would be both time consuming and expensive. And fourth, because the city of interest in the study is of a similar size and population density as Johnson City, making it almost like a sister city, and as such a great blueprint for creating an analysis for a small city.

The required inputs for this method of analysis are few in number. The first being the number of tourist. This means we need to be able to calculate or estimate the total number of attendees at each tournament, as expenditures often increase as the number of party members increase. However, just as important as the number of attendees itself, we need to know how many of those attendees are non-local. This is because in economic analysis, we cannot count money that is already circulating in the region. This means that if a tournament were to take place at Winged Deer Park, but all the attendees originated from Johnson City, then there would be no measurable impact from the tournament on the local economy because the money would have been spent in the economy either way. For this reason, we must estimate to some degree of accuracy how many non-local attendees come to each tournament in order to obtain the most accurate impact estimates.

The next input we need using this method is average spending per visitor. Fortunately for us, some amount of this information we can obtain locally through visitJC, an governmental agency that collects data on the region, including tourism data. For events that we do not have data on or for which data cannot be provided, we can rely on secondary studies once we adjust the spending to our region.

Lastly, we need the appropriate multiplier and capture rate. This is where the methods in the study begin to deviate from methods outlined in other studies. Here, the multiplier, instead of being produced by using an Input/Output model, they refer to another study (Chang) in which a multiplier for the tourism industry was calculated that relies on the population for the region in which the analysis is being performed and the population density of the region.

We will explore this further in the preliminary calculations section, but for now, its just important to note that this method does not rely upon the Input/Output tables. In addition to the multiplier, we need the capture rate for this method, which is also obtained via a secondary study.

Knowing all of this we can begin to focus on the deficiencies in our own data set.

For starters, being able to find the total spending per party, which we currently don't have. The values for spending in our current data set come from the tables presented in this study, and it is important to note those tables were generated in 2012. Not only has the cost of living increased in this time, but this is also long enough that changes in consumer spending habits should also be taken into consideration. If necessary we can still use this data, we can just adjust the cost of 2012 dollars to current value. For the sake of presenting the most up to date information though, we will continue to explore local sources of information in the hopes of obtaining local and current data.

We also need to segment our data by event type. That is easy at the moment as we only have one event type, and that is baseball tournaments. We can bring in local softball information as it becomes available, but for the soccer data, all information will have to be gathered from secondary sources as non exist from local sources.

Once we have this information we then need to find the non-local percentage of attendees. While some of this information may be available from local sources, we will most likely need to find it from a secondary source. This, like most of the other information in the tables needs to be calculated by event type. It is important to segment the information by event type as often the numbers change based on the event. Keeping these separate will allow them to be calculated more accurately and then can be summed together to find the total estimated impact.

Another point of reference has been “The Economic Impact of 30 Sports Tournaments, Festivals, and Spectator Events in Seven US Cities” by Crompton and Lee. In the study, Crompton and Lee bring to light

some important considerations for a study of this type.

One of the main ones being, and rather important to our goals, is that the economic impact on a community when a tournament does not require an overnight stay is small. Typically one should not expect expenditures for these trips to exceed a range of 55 to 100 dollars (in 2000 USD). A follow up to this point is that a large event with a large amount of attendees is unlikely to have a large impact or any impact if ‘time-switchers’ are not accounted for.

Even more importantly however, the authors outline key principles to adhere to in order to avoid mistakes made in other studies that create overestimates of impact:

- * Exclusion of local Residents
- * Exclusions of Time Switchers
- * Use of Income rather than Sales(Output) Measures
- * Careful Interpretation of Employment Measures

In addition to these principles, there are a couple of other points that the authors bring up that would be worth consideration:

- * Adult Tournaments typically involve higher expenditures
- * Softball had roughly double the rate of expenditure as soccer
- * Soccer requires no very little equipment so the opportunities for commodification are few
- * For small and medium sized communities that lack resources to stage large scale festivals sports tournaments are likely to be a superior means of generating positive local impact
- * A larger proportion of sports tournaments are more likely to recognize positive impact versus large scale special events
- * Existing staff at hotels, restaurants, retail establishments etc. are likely to have the spare capacity to handle any visitors that result from a tournament. Even if they do not a manager will reorganize shift schedules or pay overtime. ONLY IF these adjustments are unable to accommodate additional jobs will these businesses hire additional workers. This is why the Employment multiplier must be interpreted carefully.

This study also presents us with another example of how to create our table and what information it could contain when attempting to perform an economic analysis for sporting tournaments. Overall this has been an invaluable asset in terms of laying additional groundwork for how to best proceed with the presented problem.

The last study which we have been relying upon is “Economic Impacts of Tourism: A Handbook for Tourism Professionals” by Stynes. As the title of the study suggest, this has been a handbook to guide us through the process of variable selection and understanding not only how to perform an economic analysis but understanding what it is and the best practices surrounding its creation. This is also the study that the capture rate previously mentioned was generated from. It is important in understanding how the capture rate is actually calculated as the previous study shed no light on the subject, but it is just as important to note that the capture rate does not apply to our economic analysis. The reason why is due to the fact that the capture rate is used to ‘capture’ the leakage in a regional economy due to goods and services that are consumed within the region being produced outside of the region. For instance, if a person spends \$100 at a bakery, but the bakery buy all of its dough/ingredients from out of town, then this cut the circulation of that 100 within that region. Since multipliers rely on the circulation of money within an economy to generate positive impact, then this effectively reduces the multiplier. That being said, since we are using RIMS II, we do not have to worry about calculating the capture rate as RIMS II multipliers account for leakage. More on this in the section about the Input/Output Models.

Capture rate aside, this study has proven to be extremely useful as a guide, not only on what various methods are but the considerations to keep in mind when attempting to select a method or perform an analysis.

Part 3 Preliminary Estimates

In this section we will briefly cover some of the preliminary calculations made with the data set. Be aware that these calculations are extremely rudimentary and follow the procedure as well as borrow some of the data from another study. This is being highlighted as it is important to understand that these estimates may be highly inaccurate and may in no way reflect the actual impact. It should also be mentioned that none of these calculations will be used for the final estimates as we will be making use of the RIMS II multipliers and therefore do not have to calculate our own. This will be discussed further in the section covering the Input/Output model.

For our preliminary calculations we followed the methods outlined in (Brewer/Freeman), but since we only had data for the baseball tournaments then this is what we applied the method to. As such, these estimates are only for the baseball tournaments that occurred for 2022 and 2023 and do not include any data on softball or soccer.

Following the outlined methods, we began our analysis by finding the population of Johnson City (important to note the city population and not the county population was used here). For Johnson City the most current US census data gives us a value of 71,278(2021). The population density was also derived from census data, and for Washington County we have a population density of 0.4074(in thousands). Having found both the population for the area of interest as well as the population density, we can use Chang's Formula as outlined. This formula is:

$$Chang's Multiplier : 1.566 + (0.53 * \ln(POP)) - (0.0009 * POPden)$$

Where:

* POP is the regions populations in millions

* POPden is the regions populations density in thousands

With our values inserted into the equation we found the following:

$$1.566 + (0.53 * \ln(0.071278)) - (0.009 * 0.4074) = 1.42583$$

This multiplier attempts to replicate the multipliers found using Input/Output models such as RIMS II, IMPLAN, or MGM. However, this multiplier is cost effective as the cost of these models varies and for small departments in small cities the cost can be prohibitive. As such this is an excellent substitute and gives a reasonable degree of accuracy. Likewise, since we are not using a multiplier derived from a table for this initial estimate, this means that we must also use a capture rate to account for leakages in the region. Here, we just assumed the 60-70% capture rate found by Styne, discussed previously. This is easily accomplished by multiplying the upper and lower range percentages by Chang's Multiplier to adjust the multiplier effect. Some of the assumptions we made when performing these calculations:

* Day Spending Average per party = 206

* Non-local Percentage = 89%

* Overnight Spending was found by multiplying the duration of the tournament in days by the average daily expenditures

These assumptions lead us to values of:

\$4,430,894.37 for the 2022 year,

and,

\$3,099,362.70 for the 2023 year

Applying the multipliers as discussed above yields:

$$0.6 * 1.42583 * 4430894 = 2022ImpactLowerRange$$

$$0.7 * 1.42583 * 4430894 = 2022ImpactUpperRange$$

And we can do the same for the 2023 data:

$$0.6 * 1.45283 * 3099362 = 2023LowerImpactRange$$

$$0.7 * 1.45283 * 3099362 = 2023UpperImpactRange$$

These calculations yield the following values:

* 2022 Range: (3790620,4422390)

* 2023 Range: (2651500,3093410)

* Combined: (6442120,7515800)

It is important to note that these calculations only include the data given so far. This means that this estimate is for the tournaments that have previously taken place on the current 5 baseball/softball field setup. For the purposes of the economic impact analysis we will be creating additional estimates that hope to capture the impact the expansion will bring. Those estimates will be produced using Multipliers from the RIMS II Input/Output model. However, this does give us some preliminary insights into the impact that sports tourism, even on a smaller scale, has on the region. Further, we see that give the cost of maintaining the fields themselves is absorbed by the department, however the regional impact is far greater than the cost associated with said maintenance.

Additional calculations made further in the project will be separate for each sport, and potentially for each age group depending on how great the difference is for spending between ages. These numbers will then be summed to find an overall impact estimate for all tournaments. Then, this impact estimate will be multiplied by the appropriate multipliers in order to gain further insight into the impact on the regional economy.

Part 4 Input/Output Models

Here we hope to go into some detail about what an Input/Output model is, and what is used for in economic analysis.

The Leontief matrix, also known as the Input-Output matrix or the Leontief input-output model, is a fundamental component of input-output analysis in economics. It was developed by the Russian-American economist Wassily Leontief in the 1930s as a way to model the interdependencies among various sectors of an economy. The Leontief matrix represents the flow of goods and services between sectors within an economy.

Here's a more detailed explanation of the Leontief matrix and its key components:

1. Matrix Structure:

- The Leontief matrix is a square matrix, meaning it has the same number of rows and columns.
- Each row and column in the matrix corresponds to a specific economic sector within the analyzed region or economy.

2. Elements of the Matrix:

- The elements (entries) of the matrix represent the amount or value of goods and services purchased by each sector from all other sectors, including itself.
- Typically, the entries are represented as a_{ij} , where “i” refers to the row (the purchasing sector) and “j” refers to the column (the selling sector).

3. Interdependence:

- The Leontief matrix captures the interdependence of economic sectors. It shows how much each sector depends on other sectors for intermediate inputs.
- For example, the construction sector might purchase steel from the manufacturing sector, and in turn, the manufacturing sector might purchase construction services for its buildings. This interdependence is reflected in the matrix.

4. Diagonal Elements:

- The diagonal elements (a_{ii}) represent the “self-purchases” of each sector. This is the amount of goods and services a sector produces and consumes itself.
- Self-purchases are usually found on the diagonal of the matrix because each sector buys from itself.

5. Off-Diagonal Elements:

- The off-diagonal elements (a_{ij} , where $i \neq j$) represent the purchases by one sector from another sector. These entries quantify the flow of goods and services between sectors.

6. Use in Economic Analysis:

- The Leontief matrix is a critical tool for economic analysis, especially for input-output analysis and computable general equilibrium modeling.
- It allows economists to estimate the ripple effects of changes in one sector on the entire economy. For example, if there's an increase in consumer demand for automobiles, the Leontief matrix can help calculate the resulting increase in production and employment in the automotive sector, as well as its effects on other related sectors.

7. Multipliers:

- The Leontief matrix is used to calculate economic multipliers, such as the output multiplier, income multiplier, and employment multiplier. These multipliers show the total economic impact of changes in demand or production in a specific sector.

8. Data Source:

- The data used to populate the Leontief matrix comes from various sources, including national or regional economic surveys, input-output tables, and industry reports.

Some of the assumptions the RIMS II model uses when generating its multipliers are:

Backward linkages.

I-O models can measure the impact of an industry's production on other industries in two ways. In a backward-linkage model, an increase in demand for output results in an increase in the demand for inputs. In a forwardlinkage model, an increase in the supply of inputs results in an increase in the supply of output. RIMS II is a backward-linkage model. To give an example of the impact measured by RIMS II, consider the expansion of a warehouse. The impacts of the expansion estimated with the model's multipliers will account for the increase in demand for inputs by the warehouse but will not account for the increase in production by the industries that may use the warehouse.

Fixed purchase patterns.

I-O models assume that industries do not change the relative mix of inputs used to produce output. They also assume that industries must double their inputs to double their output. If industries can increase their output without hiring as many workers as the model assumes, then using the model's multipliers will produce inflated impact estimates. These assumptions are a particular concern for industries that employ many parttime or seasonal workers. These industries can often extend the hours of existing workers rather than hire as many workers as the model assumes, particularly if an increase in the demand for an industry's output is viewed as temporary. Another concern relates to estimating impacts of events that are large enough to alter the structure of a regional economy, such as a catastrophic event or the departure of a major industry. Because the purchase patterns in the model are measured before such events, impacts estimated with the model's multipliers will not adequately capture the new relationships among industries in the region.

Industry homogeneity.

I-O models assume that all businesses in an industry use the same production process. If the production process of the business initially affected by a change in economic activity is not consistent with the production process of the industry in the national I-O accounts, using RIMS II multipliers will yield inaccurate impact estimates. This assumption raises concerns of aggregation bias in I-O models with less industry detail. As industries are grouped together, the same production process is assumed for a wider range of industries. This practice can also assign production to local industries where none actually exist. These concerns suggest that detailed multipliers should be used unless there is a good reason to do otherwise.

No supply constraints.

I-O models are often referred to as “fixed price” models because they assume no price adjustment in response to supply constraints.² In other words, businesses can use as many inputs as needed without facing higher prices.

Local supply conditions.

RIMS II is based on national I-O relationships that are adjusted to account for local supply conditions. These adjustments account for the fact that local industries often do not supply all of the intermediate inputs needed to produce the region’s output. Industries must purchase some intermediate inputs from suppliers outside the region. These purchases are often called leakages because they represent money that no longer circulates in the local economy. RIMS II accounts for these leakages by considering each industry’s concentration in the region relative to its concentration in the nation. This method does not explicitly account for what is often called cross-hauling. Cross-hauling is when a good or service is both an import and an export of a region. To give an example of how cross-hauling can affect an economic impact study’s results, consider a construction project that uses windows that are manufactured outside the region. If windows are manufactured in the region, the model assumes that these windows are purchased rather than those manufactured outside the region. In this case, using RIMS II multipliers is likely to produce inflated impact estimates.

No regional feedback.

RIMS II is a single region I-O model. It ignores any feedback that may exist among regions. To give an example of how regional feedback can affect an impact study’s results, consider a construction project that requires wrought iron fencing that is manufactured in a second region. If the fence manufacturer purchases accounting services from the first region, these services will not be accounted for in the impact estimated for the construction project using multipliers for the first region. It is unclear how the results of an economic impact study are affected by regional feedback without knowing the details of how a region is economically related to other regions. Choosing a study region that is large enough to encompass a group of interrelated industries can ease concerns of possible feedback effects.

No time dimension.

The length of time that it takes for the total impact of an initial change in economic activity to be completely realized is unclear because time is not explicitly included in I-O models. The actual adjustment period varies and is dependent on the initial change in economic activity and the industry structure that is unique to each region. The initial change in economic activity should be permanent or at least persistent enough

to fully work through the economy. If the change is not persistent, which is often the case with short-term projects and events, local businesses are likely to hire fewer workers and purchase fewer intermediate inputs from the region than the I-O model assumes.

Additionally, some notes about the multipliers the Input/Output model generates:

FINAL DEMAND MULTIPLIERS:

In addition to the final demand output multiplier, there are three other types of multipliers: Earnings, Employment, and Value added.

Earnings:

Consist of wages/salaries/proprietors income. Employer contributions to health insurance are included.

The Employment Multiplier:

measures the total change in the number of local jobs per dollar of final change

Value added:

Comparable to regional GDP

When talking about final demand, this consist of a few different types of transactions that are incorporated into the model:

1. Purchases by consumers outside of the region.
2. Investment in new buildings, equipment, and software
3. Purchases by government
4. Purchases by households.

Additionally, there are Type I and Type II multipliers to consider as they are calculated to reflect different changes in the economy. For more detail about the multipliers generated by the Input/Output models:

Example of Multiplier:

The sales multiplier for the lodging sector was 1.74 for the state of florida in 1996. That means that a visitor spending \$100 on lodging will have total effects of 174 on sales within the state. That is, 100 received by the hotel as a direct effect, and 74 received by other related industries in the region through secondary effects.

Direct effects are changes in the industries associated directly with visitors spending. In the previous example, \$100 spent on lodging will directly increase sales in the lodging sector. This is the direct sales effect of the visitor spending. The hotel will also hire employees, pay wages and salaries, which are the direct job and income effects.

Indirect and Induced effects: are the secondary effects resulting from the initial visitor spending. Indirect effects are sales income or jobs resulting from various rounds of purchases the hotel made to other “backward linked” industries in the region.

Induced effects are the sales income and jobs resulting from household spending of income earned as a result of visitor spending either directly or indirectly.

*** Type 1 multipliers only capture the indirect effects, Type II multipliers include both induced and indirect effects.

But what does all of this mean for our model? So far we have the following assumptions:

Investment purchases exclude maintenance and repair expenses because these expenses are treated as intermediate inputs in RIMS II.

FINAL DEMAND CHAGE:

This change is the expected increase in tourism. Because the expansion at Winged Deer park is not expected to draw people from other local programs, this increase does not need to be reduced to account for loses to other regional programs. Most of the tournament participants are expected to come from outside the area, so this increase does not need to be reduced to exclude the purchases of tournament services by local residents.

**TAXES AND SAVINGS are accounted for in the multiplier

FINAL DEMAND INDUSTRIES:

Food, Hotel and Lodging, Retail(excluding wholesale), Entertainment/Amusement

MULTIPLIER TYPE: TYPE II

FINAL DEMAND REGION:

Washington County, TN

As we continue to learn more about Input/Output models, their multipliers, and their implementation, the assumptions we currently have will change to reflect this change in understanding. However, at the moment we have developed a functioning understanding of Input/Output models and as such can provide economic analysis utilizing the tools available to us and used throughout the industry for the same purpose. In the end, we aim to produce a professional quality analysis that can provide meaningful insight into the tourism impact for our region, and better equip the parks and recreation department with information it can use to better understand the demand and impact of its services.

Part 5 Moving Forward

In this report we have covered the initial data set we received from the parks department, the secondary studies which we have referenced to gain insight into how to perform an economic analysis for the sports tourism industry on a regional level, the initial calculations and findings with our data set, and we have delved into Input/Output models and shared what we know to date. But that brings up the question, what is next?

For now, one of the goals we would like to accomplish is the distribution and retrieval of a survey we have created in order to gain fresh data. The secondary studies provide excellent information, however the most recent of them is from 2012. Cost and consumer behaviour would be a nice thing to account for in our model. As such we have created a survey in order to capture the parameters of interest so that we may have current data to add to our data set, and so that our assumptions are based off of current day behavior. Primarily we are interested in capturing how far a person is willing to travel before they would be willing to stay the night for a tournament. Additionally we want to try and capture how many people usually travel with the player, especially if we can make a distinction by age group. And of course, we want to try and estimate how much they would typically spend during one of these trips. Depending on the response rate we may or may not use the data received from the survey, but we will have to wait for responses to see.

On top of the economic impact analysis, it looks as if we will also need to perform a financial impact analysis, which is fortunately a little more straight forward as it fore goes the use of the multipliers, but will have more parts as it will be aimed at trying to calculate what the park can expect its annual revenues and expenditures to be given a particular number of events in a year. This information has to be calculated separate from the economic impact analysis, as some of the assumptions made for creating the multipliers actually effect the outcome for the department. So, this will be another component of the study, and a component the parks and rec department can use to determine fee structures for tournaments.

We will also continue to reach out to regional sources to try and expand our data set this way as well. Not only this, but we will continue to reach out to industry experts in order to solidify our understanding of the task at hand and by extension create the most accurate analysis possible. All additional information that is relevant to the analysis will be added to the data set upon acquisition. A secondary data set may be constructed that contains information relevant to the financial impact study, but more information will have to be obtained before this decision is made.

For all information that cannot be obtained we will use information available from secondary studies, making sure to adjust all dollar values for both inflation and region. While this is not the preferred method this should still result in an analysis that contains estimates of an acceptable accuracy.

And for all analysis performed we will create visualizations to accompany them for ease of presentation.
